Abstract

This paper discusses pitfalls in two-way fixed effects (TWFE) regressions when the outcome variables contain nonlinear and possibly stochastic trend components. If a policy change shifts trend paths of outcome variables TWFE estimation can distort results and invalidate inference. A robust solution is proposed by allowing for dynamic club membership empirically using a relative convergence test procedure. The determinants of respective club memberships are assessed by panel ordered logit regressions. The approach allows for policy evolution and shifts in outcomes according to a convergence cluster framework with transitions over time and the possibility of eventual convergence to a single cluster as policy impacts mature. The long run impact of a policy can thus be examined via its impact on convergence club membership. An application to new weekly US Covid-19 vaccination policy data reveals that Federal-level vaccine mandates produced a merger of state vaccination rates into a single convergence cluster by mid-September 2021.

1 Introduction

Two-way fixed effects (TWFE) regressions are commonly used in empirical work, particularly to evaluate the effectiveness of exogenous policy change. Several outcome variables are often examined in such regressions and policy effectiveness is measured through its potential impact on dependent variables that may themselves involve stochastic trends such as random walks or similar random processes with nonlinear trend components. Examples of such variables are personal wages, state per capita income, and life expectancy data, all of which are popular in practical work because of their immediate relevance in policy determination or more general interest in social science studies. For a recent estimate of such work we counted the number of published papers that employed nonstationary outcome variables in the January 2023 issue of the AEJ: Applied Economics. Of the 16 articles published in this issue all but one used TWFE regressions. Among these, 12 papers used nonstationary outcome variables including log earnings, log wages, median income and crop output; and some 86% of the papers using TWFE regressions employed nonstationary dependent or outcome variables.¹

To fix ideas suppose y_{it} is a relevant outcome variable comprising a sequence of panel observations of interest across individuals $(i = 1, \dots, n)$ and over time $(t = 1, \dots, T)$ and let x_{it} be a relevant policy variable. A typical TWFE regression specification for analyzing such data takes the form

$$y_{it} = a_i^o + \theta_t^o + \beta x_{it} + \gamma' z_{it} + v_{it}, \tag{1}$$

where a_i^o and θ_t^o are individual and time specific effects, and z_{it} is a vector of control variables. When the policy x_{it} has the form of a panel dummy variable, some pitfalls in TWFE estimation have already been studied in recent work De Chaisemartin and d'Haultfoeuille (2020); Goodman-Bacon (2021). The present paper extends that research by considering more general and empirically relevant cases where the policy variable x_{it} may itself evolve over time and where the outcome variable y_{it} may have nonstationary characteristics sourced beyond the policy input. In complex applied work where the nonstationarity in outcomes is not fully captured by policy inputs or time specific effects, the regression residual v_{it} becomes nonstationary and the adequacy of TWFE regressions in accurately measuring policy effectiveness may be called into question.

Previous studies often bypass such complications by assuming a small fixed T, frequently just T=2 observations, and allowing a large cross section sample size n to deliver asymptotics. In cases like the recent Covid-19 pandemic experience successive policy changes over time need to be accommodated in the data analysis and longer time series samples are available for assessing the

¹Amongst individual household earnings or wages only a small fraction may have nonstationary characteristics but as these time series are aggregated nonstationary characteristics tend to stand out and become more dominant as the aggregation level successively rises from suburbs to cities and counties. See Sul (2019) for discussion.

evidence of successive policy effects in the observed outcomes. Our empirical study has T=40 and n=51 observations, so that cross section and time series sample sizes are comparable. This paper studies cases where trends are homogeneous and heterogeneous over individuals under the null of no treatment effect or no policy effectiveness. Under the alternative, policy variables influence outcome variables either in levels (C1) or in trends (C2). If a stationary policy variable affects a nonstationary outcome variable in levels (C1), the policy effectiveness does not last long, holding only temporarily. In this case, TWFE regression is valid only under a homogeneous trend with consistent estimation and valid standard errors as $n \to \infty$. But the properties of estimation and inference are less favorable when the outcome variables are nonstationary with heterogeneous trend behavior. A partial solution is straightforward under the assumption that policy variables affect outcomes only in levels. For level effects can be consistently estimated either under homogeneous or heterogeneous trends using the differenced regression

$$\Delta y_{it} = a_i + \Delta \theta_t^o + \beta \Delta x_{it} + \gamma' \Delta z_{it} + \Delta v_{it}, \tag{2}$$

However, it is unrealistic to expect that policy variables affect outcomes only in levels. When policy affects trend behavior of the outcome variables, the first difference TWFE regression (2) is misspecified, leading to inconsistent estimation of policy effects.

Our study considers several issues that bear directly on TWFE and difference-in-difference (DiD) treatment effect analysis. The primary concern examines outcome variables when stochastic trend components are omitted from the regression and when heterogeneous trend behavior over time or across individuals affects outcomes. In both cases, the TWFE system is misspecified, leading to growing uncertainty and inconsistent estimation. A typical DiD approach² to resolving this issue is to employ first difference outcomes or growth rates while maintaining the same policy variable, so that the TWFE regression now takes the form

$$\Delta y_{it} = a_i + \theta_t + \beta x_{it} + \gamma' z_{it} + u_{it}, \tag{3}$$

in which the influence of x_{it} on the growth rate of y_{it} is studied. This approach leads to a further pitfall which arises when the outcome y_{it} has nonlinear trend behavior. First difference TWFE regressions, either in (2) or (3), typically examine short run responses by removing presumed long run stochastic trend (unit root process) relationships, which may not be well suited to other long run behavior. For instance, suppose that a certain policy change has a positive effect only for a

²In the DiD or event-study regression literature, several devices have been proposed, which are well surveyed in the recent review by Roth et al. (2023) and an alternative solution allowing for violation of the parallel trends assumption is considered in Rambachan and Roth (2023). Our approach allows, in addition, for policy evolution and shifts in outcomes over time according to a convergence cluster framework with transitions over time and the possibility of eventual convergence to a single cluster as policy impacts mature.

short period but produces a negative impact on the outcome variable in the long run. In such a case, TWFE estimation as in (3) can mistakenly lead to an implied positive impact even for large T, as demonstrated later.

One of the main contributions of the paper is to provide a methodology that organizes nonstationary panel data into ordered panel multinomial variables by means of a dynamic clustering mechanism that allows for shifts in clusters over time. To fix ideas, define C_{it} to be the convergence club membership in period t of the i-th individual and suppose all individuals within a certain convergence club share the same stochastic trend. If an individual grows faster over time and joins another convergence club that attains higher outcomes, then C_{it} membership changes over time. The convergence clustering mechanism (CCM hereafter) proposed in earlier work by Phillips and Sul (2007a, hereafter, P-S) transforms statistics from panel observations to clustered cross-sections, but potential dynamic changes amongst club memberships are ignored. In practice, club membership can change over time, particularly as relevant policies are introduced or evolve over time, and such evolution can itself be a natural focus of interest concerning policy impacts. Our approach in the present paper is to develop the CCM of P-S into a dynamic version that accommodates such possibilities. Once dynamic group membership is estimated, panel logit (or multinomial logit) regression enables estimation and inference concerning driver variables and the determining mechanisms of the groups. The proposed method can be used with either event-study (DiD) or continuous policy interventions. The approach is also robust against functional forms with heterogeneous trends as long as C_{it} membership is well defined.

A second main contribution of the paper is to create a new weekly database that tracked state and District of Columbia announcements of the numerous vaccination policies³ implemented over the period from March 2021 to February 2022. This database enables a detailed empirical study of the impact of federal and state vaccination policies on state vaccination rates. A final contribution is technical and relates to the use of logarithmic transformation of the data. In particular, we consider the use of logarithms of ratios in panel data and provide a simple procedure for dealing with the practical problem of logarithmic representations when a few data points are zero or negative.

The rest of the paper is organized as follows. Section 2 considers issues arising from nonstationary outcome variables and pitfalls in the use of first differences in policy evaluation. Dynamic mechanisms for club membership are developed in Section 3. Section 4 consists of two subsections. The first subsection discusses data preparation and some useful new adjustments in logarithmic transforms and then second subsection provides an application of this mechanism to state vaccination rates over time in the United States. Panel logit modeling is applied to assess the effects of U.S. federal level mandate announcements and various state level COVID-19 vaccine policies on

³These policies included lotteries, cash for vaccination incentives, community outreach programs, vaccine mandates for state employees and or healthcare workers, indoor vaccine mandates or mandates for gatherings over a certain number of people, mask mandates, bans on proof of vaccination, and bans on mask mandates.

state convergence club membership. Section 5 concludes. Federal and state level mandate policies are described in Appendices A and B, and additional logit regression specification results are given in Appendix C. Technical background, derivations, proofs and further simulations are provided in the Online Supplement to this paper.

2 Pitfalls of TWFE Regressions with Nonstationary Outcomes

Throughout the paper we assume that the dependent or outcome variables are nonstationary, whereas the policy variable is stationary.⁴ We consider the following three general models allowing nonstationary outcomes when a policy variable does not influence y_{it} (i.e., under the null hypothesis):

$$y_{it} = \begin{cases} a_i + t + \xi_{it}, \, \xi_{it} = \xi_{it-1} + u_{it} & \text{for M1,} \\ a_i + b_i t + \xi_{it}, \, \xi_{it} = \xi_{it-1} + u_{it} & \text{for M2,} \\ a_i + b_{it} t + \xi_{it}, \, \xi_{it} = \xi_{it-1} + u_{it} & \text{for M3,} \end{cases}$$

$$(4)$$

where the nonstationarity includes heterogeneous deterministic trend functions as well as a stochastic trend. Specifically: in M1, y_{it} has a homogeneous linear trend; in M2, y_{it} has a heterogeneous linear trend with time invariant individual coefficients b_i ; and in M3, the individual trend coefficients b_{it} are time varying, which nests M1 and M2. A policy variable, x_{it} , is assumed to be stationary. One may introduce a staggered or continuous trend to x_{it}^5 , but such modifications do not alter the main results of the paper.

Under this framework there are two mechanisms by which the stationary policy change can affect the nonstationary outcome under the alternative: (i) x_{it} can affect the level of y_{it} (designated C1, as above); and (ii) x_{it} can affect the trend coefficient b_{it} (designated C2). Under the null of no policy effectiveness, the outcome variables are given by (4). In this case the parameter β , which measures the policy impact in the following equations, is zero. The two alternative cases are written as follows.

$$y_{it} = a_i + \theta_t + \beta x_{it} + \xi_{it} \text{ for C1}, \tag{5}$$

$$b_{it} = b_o + \beta x_{it} + e_{it} \text{ for C2}, \tag{6}$$

where θ_t in (5) may be a linear or more general deterministic trend and b_{it} are the trend coefficients in M3. We consider C1 in the next subsection, showing that if the true generating process is either

⁴As shown later in the empirics, key policy variables often tend to change in a staggered manner over time. After removing the steps these variables are typically flat or stationary about certain levels. As such, they impact outcome variables only temporarily. On the other hand a policy that switched on and off at different levels of intensity could produce nonstationarity in mean.

⁵As shown in Figure 3 there were staggered increases in the Federal vaccine mandate, whereas the vaccine lottery had been in decline continuously after July in 2021.

M1 or M2, a first difference regression can account for the nonstationary process in C1. C2, however, is a more realistic formulation that has been used by labor and health economists in situations a stationary policy affects the long run behavior of outcome variables. For example, Abadie et al. (2010) showed that California's tobacco control program changed the slope of the trend in tobacco consumption. In such situations first difference regression fails, as shown in Section 2.2 below. An alternative solution is provided in Section 3.

2.1 Policy influence only on levels: C1

This model has been popularly considered in the treatment effects literature. Without a homogeneous trend assumption, difference-in-difference estimation fails to identify the treatment effects. Even with homogeneous trends, when a policy variable x_{it} is stationary in a model such as (5), it is not a long run determinant of the outcome variable and impacts the outcome only temporarily. An empirical example of this phenomenon was the 'Cash for Clunkers' program implemented in the United States in 2009. Under that program, eligible car owners were given a substantial rebate to trade in their old cars for new ones. The purpose of the program was twofold: to stimulate a weak economy by encouraging car sales, and to reduce CO_2 emissions by getting rid of older, less fuel efficient cars. The program caused a temporary, moderate increase in new car sales during the two months it was in place, however there was no increase in overall car sales for the year. Essentially, some people who would have bought a new car anyway that year did so in the couple of months the program was in place rather than spreading their purchases across the year. The end result in new car sales was no different than it would have been in the absence of the program (Li et al. (2013)).

Against this background consider the following TWFE regression frequently used in applied research:

$$y_{it} = a_i + \theta_t + \beta x_{it} + v_{it}, \tag{7}$$

where θ_t is a time fixed effect and the regression error v_{it} in (7) is the stochastic trend ξ_{it} . Let $\hat{\beta}_l$ be the TWFE estimator of β in (7). To simplify notation, rewrite (7) in differenced form as

$$\dot{y}_{it} = \beta \dot{x}_{it} + \dot{v}_{it},\tag{8}$$

where $\dot{y}_{it} = y_{it} - \frac{1}{T} \sum_{t=1}^{T} y_{it} - \frac{1}{n} \sum_{i=1}^{n} y_{it} + \frac{1}{nT} \sum_{i=1}^{n} \sum_{t=1}^{T} y_{it}$, with similar definitions for the other variables. This within-group transformation does not remove stochastic nonstationarity but it does eliminate heterogeneous individual fixed effects and any homogeneous (over individuals) trend. The consequences of using this type of TWFE regression with a policy variable x_{it} in place (such as the 'Cash for Clunkers' program) arise from the fact that the regression is ill-balanced because stochastic trend effects remain in \dot{v}_{it} and are transmitted to \dot{y}_{it} , making policy effects only temporary. The lack of balance induces a reduction in the signal to noise ratio that affects the accuracy of the TWFE

estimator, $\hat{\beta}_l$. The properties of $\hat{\beta}_l$ depend in this case primarily on the cross section sample size n, so that increases in the number of time series observations do not help to shrink the variance of $\hat{\beta}_l$. More formally, as $n, T \to \infty$, when x_{it} affects y_{it} only in levels as in (5), the limit distribution of $\hat{\beta}_l$ is given by

$$\sqrt{n}(\hat{\beta}_l - \beta) \to \mathcal{N}(0, V_\beta),$$
 (9)

with asymptotic variance V_{β} shown in the Online Supplement (Theorem 1). A panel robust variance estimator, clustering by time, can be used to consistently estimate V_{β} .

Next, consider the heterogeneous trends case M2. Many dependent variables used in empirical TWFE regressions can be expected to involve heterogeneous trends in the data. For example, if the unit of observation is counties, and the dependent variable is obesity levels, the slope of obesity growth almost certainly varies county by county. This heterogeneity in trends is a complication that affects asymptotic behavior and finite sample performance even when some of the regressors themselves include trends. As long as time-homogeneous coefficients are assumed in estimation, the regression error carries the effects of heterogeneous trends, leading to failure in standard limit theory and inference. To illustrate, suppose y_{it} is generated from

$$y_{it} = a_i + b_i t + \beta x_{it} + \xi_{it}, \tag{10}$$

where ξ_{it} is nonstationary.⁷ Then the induced TWFE residual in (8) includes a trend term under the null $\beta = 0$, i.e.,

$$\dot{v}_{it} = (b_i - \frac{1}{n} \sum_{i=1}^n b_i)(t - \frac{1}{T} \sum_{t=1}^T t) + \dot{\xi}_{it}, \tag{11}$$

so that cross section variation of \dot{v}_{it} grows at an $O(t^2)$ rate even when ξ_{it} is stationary. When x_{it} affects y_{it} in levels under heterogeneous trends, the asymptotic behavior as $(T, n) \to \infty$ of $\hat{\beta}_l$ are shown in Theorem 3 of the Online Supplement to have the following form

$$\sqrt{n}(\hat{\beta}_l - \beta) = O_p(T^{1/2}) + \mathcal{N}(0, V).$$
(12)

To examine the empirical implications of these asymptotic findings, we use log COVID-19 vaccination data across 50 US states – see the empirical section for a detailed explanation of the data. We also ran a Monte Carlo simulation with 50,000 replications to explore test size, giving rejection frequencies of the null hypothesis when the null is true. For each replication, a random policy variable x_{it}^* was generated from a standard normal distribution. The outcome variable is

⁶In this regression, the signal from the sample variance of \dot{x}_{it} is dominated by the sample covariance of \dot{x}_{it} and \dot{v}_{it} because the regression error is nonstationary. See the Online Supplement for further analysis.

⁷The asymptotic results do not change even when ξ_{it} is stationary under heterogeneous trends

Table 1: Monte Carlo Simulation Results of Level Effects with Nonstationary Errors

Power	10	0.492	0.190	0.909	0.911
	15	0.519	0.174	0.981	0.981
	20	0.526	0.160	0.996	0.997
	25	0.533	0.154	1.000	0.999
	40	0.543	0.137	1.000	1.000

constructed as follows. First, we computed the cross section average $\hat{\mu}_t = \frac{1}{n} \sum_{i=1}^n y_{it}$ of the log vaccination rates across states. Next, we generated pseudo vaccination rates as

$$y_{it}^* = \begin{cases} a_i + \hat{\mu}_t + \xi_{it}, & \text{for M1,} \\ a_i + b_i \hat{\mu}_t + \xi_{it}, & \text{for M2,} \end{cases}$$
 (13)

where $a_i \sim_{iid} \mathcal{N}(0,1)$, $b_i \sim_{iid} \mathcal{N}(1,1)$, $\xi_{it} = \xi_{it-1} + u_{it}$ with $u_{it} \sim_{iid} \mathcal{N}(0,1)$ and $\xi_{i1} = u_{i1}$. Test power was computed from the rejection frequencies of the null when the null is false using the following data generating process:

$$y_{it}^* = \begin{cases} a_i + \hat{\mu}_t + \beta x_{it}^* + \xi_{it}, & \text{for M1,} \\ a_i + b_i \hat{\mu}_t + \beta x_{it}^* + \xi_{it}, & \text{for M2,} \end{cases}$$
(14)

where $\beta = 0.1$. In all replications n = 50 and $T \in \{10, 15, 20, 25, 40\}$.

Table 1 shows simulation findings based on (13) and (14). Under M1 (homogeneous trend) and M2 (heterogeneous trend), the size of the test seems satisfactory even for T = 10. The main difference is found in test power, as asymptotic results predict. As T increases, the power of the test based on $\hat{\beta}_l$ decreases under M2, but fluctuates under M1.8 Monte Carlo simulations support the asymptotic results that when heterogeneous trends are present variance increases with T, making

⁸Since our simulations replicate actual vaccination rates using a random ensemble, the sample sizes n and T cannot be raised greater than their actual empirical sizes (n = 50, T = 40). However, as shown in the supplementary appendix, results from standard Monte Carlo simulations mirror the asymptotic theory. As n increases, size becomes more accurate and power improves; but as T increases, size changes little. For M1, test power based on $\hat{\beta}_l$ fluctuates with T for a given n. For M2, test power actually decreases as T increases for a given n.

test power weak.

The following first difference (FD) regression can be used to restore test power:

$$\Delta y_{it} = a_i + \Delta \theta_t + \beta \Delta x_{it} + e_{it}, \tag{15}$$

or the two-way transformed form given by

$$\Delta \dot{y}_{it} = \beta \Delta \dot{x}_{it} + \dot{e}_{it}. \tag{16}$$

Importantly, the FD regression includes two way fixed effects. The individual fixed effect a_i captures potential heterogeneous trend coefficients, while the time fixed effect $\Delta\theta_t$ captures common time changes. The regression error e_{it} is now stationary. Let $\hat{\beta}_{fd}$ be the TWFE estimator in (16). It is straightforward to show that as $T, n \to \infty$,

$$\sqrt{nT}(\hat{\beta}_{\mathrm{fd}} - \beta) \to \mathcal{N}(0, V_{\beta_{\mathrm{fd}}}),$$
 (17)

where $V_{\beta_{\rm fd}}$ is the asymptotic variance of $\hat{\beta}_{\rm fd}$, which is smaller than V_{β_l} in (9). This limit theory is only valid it is known that x_{it} affects only the level of y_{it} . In practice, it may be challenging to assess whether x_{it} affects the level or the trend behavior of y_{it} or both. For when the outcome variable itself has a trend, any level change is temporary and permanent effects or long run impacts are inevitably influenced by the trend or trend coefficients. It may therefore appear reasonable to assess how a policy change affects growth rates rather than level outcomes, suggesting a TWFE regression in differences as in (2). However, if the outcome variable has nonlinear or time-variable trend behavior then TWFE regression in differences also fails to capture the impacts of a policy change. This issue is now discussed.

2.2 Policy influence on trends: C2

For further analysis of potential pitfalls in TWFE estimation consider the generating process (DGP)

$$y_{it} = a_i + b_{it}t + \xi_{it}, \text{ with } \xi_{it} = \rho \xi_{it-1} + e_{it},$$
 (18)

where intercepts a_i affect the level of y_{it} , the b_{it} are heterogeneous time varying trend coefficients, and the ξ_{it} are time series¹⁰ with a unit root when $\rho = 1$. Now suppose that a policy variable x_{it} influences b_{it} where x_{it} is a simple dummy variable. In this case, the policy changes the slope of the

⁹A more technical discussion is given in the Online Supplement.

¹⁰If the DGP (10) changes to (18), the asymptotic effects are similar but the reported simulation results deteriorate and these now depend on the variance of b_{it} .

trend in the outcome variable, y_{it} , impacting its long run trajectory. Assume $x_{it} = 0$ for all i except for i = 1 and $t \ge \tau$, which is a typical setting in the synthetic control literature. To be specific, the following empirical example highlights how a policy change influences the coefficient on the trend, or b_{it} . Figure 1 shows per-capita cigarette sales in California from 1970 to 2000, which were studied in Abadie et al. (2010). A policy intervention started in 1989. Evidently, the estimated coefficients on the trend changes suddenly after the policy intervention, changing the long run trend in cigarette sales. This simple example demonstrates how a policy dummy can influence the trend coefficient that drives the long run behavior of an outcome variable. Naturally, the policy change affects y_{it} permanently as long as ξ_{it} is stationary.¹¹

0 after
0 before

fitted trend (after)

60

Figure 1: Smoking policy in California and per-capita cigarette sales

Note: The fitted trend regression before 1989 is 3246 - 1.58 × t where $t = 1970, \dots, 1988$. Meanwhile the fitted trend after 1988 is 7147 - 3.55 × t with $t = 1989, \dots, 2000$. Hence $b_{it} = 3246/t - 1.58$ if t < 1989 and $b_{it} = 7147/t - 3.55$ if $t \ge 1989$.

82 84 86

To avoid spurious effects and restore test power, as mentioned in subsection 2.1, common empirical practice is to take the first-difference of the outcome variable, y_{it} when it is nonstationary, as it is in (18). The pitfalls that can arise from the practice of taking first-differences when a policy impacts long run trend behavior of an outcome variable are a prime focus of the present paper. In C2 where x_{it} affects b_{it} , regressions either in first differences or growth rates of y_{it} fail to deliver a satisfactory proxy for the temporal impact b_{it} . For instance, taking differences of (18) gives

$$\Delta y_{it} = b_{it}t - b_{it-1}(t-1) + \Delta \xi_{it} = b_{it} + \Delta b_{it}(t-1) + \Delta \xi_{it}, \tag{19}$$

The reason for taking first-differences is to eliminate the trend from y_{it} , rendering Δy_{it} stationary.

¹¹Let \mathcal{G} be a control group. Suppose that $b_{it} = 0$ if $i \in \mathcal{G}$ but $b_{it} = 1$ if $i \notin \mathcal{G}$ and $t \geq \tau$. Then the TWFE regression with some suitable adjustments (for example, Arkhangelsky et al. (2021)) is effective since b_{it} changes only within the treated group. In this case, we can rewrite the DGP as $y_{it} = a_i + bt + \xi_{it}$ if $i < \tau$, but $y_{it} = a_i + a_i^* + b_i t + \xi_{it}$ if $i \notin \mathcal{G}$ and $t \geq \tau$. Hence in this case the modified TWFE regression is well justified unless b in \mathcal{G} is heterogeneous across i.

But when the impact of a policy is non-linear, such as when b_{it} changes at some point in time, taking first differences does not eliminate the time trend effects. Hence, regression of Δy_{it} on fixed effects (both individual and time specific) and x_{it} produces misleading findings about the impact of the policy because of the missing trend and policy effects in the component $\Delta b_{it}(t-1)$.

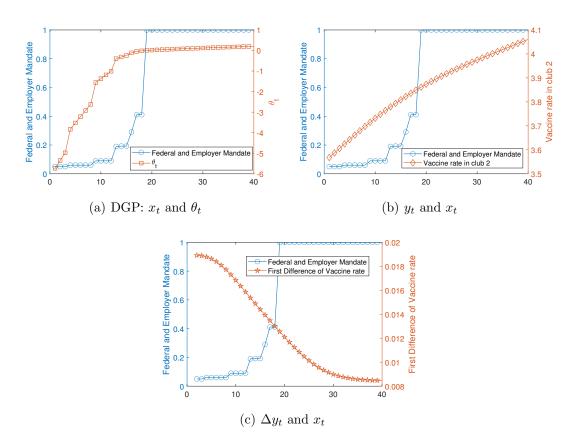

Instead of a linear trend, we can use a general nonlinear trend function. To provide an intuitive demonstration of how a time varying coefficient affects the regression, we consider a simple time series without any stochastic random variables given by

$$y_t = a + b_t \theta_t$$
, with $b_t = x_t$,

where θ_t is a unknown nonlinear trend, x_t is a policy variable, and b_t is the coefficient on the unknown nonlinear trend. As we will show later, the federal and employer vaccine mandates (FEVM) for Covid-19 vaccinations in the United States led to changes in the slopes of cumulative vaccination rates in many states. To fix ideas, let y_t be the cross-sectional average of vaccination rates in these states, which we will later call 'club 2'; and x_t is FEVM. After eliminating a by taking the time series mean of y_t , we can calculate θ_t by dividing $y_t - \frac{1}{T} \sum_{t=1}^T y_t$ by x_t . This hypothetical trend, θ_t , and x_t are plotted in Figure 2(a). As the figure shows, the calculated θ_t does not have a linear trend but rather a nonlinear trend. Next, Figure 2(b) shows FEVM and y_t . Obviously, FEVM seems to have a positive relationship with y_t , but due to the nonstationary or non-linear trending nature of y_t , this relationship is not stable in the long run as we discussed in the previous subsection. Figure 2(c) displays FEVM and Δy_t . As the figure shows, Δy_t has a negative relationship with FEVM even though θ_t is generated under the restriction of $b_t = x_t$.

To summarize, we examine the use of TWFE in nonstationary outcome variables with three different types of trends: homogeneous trends (M1), heterogeneous linear trends (M2), and our main focus, heterogeneous non-linear trends (M3). The use of TWFE with M1 will result in misleading results because any impact from x_{it} is only temporary and will not alter the long run outcomes of the variable of interest. Running a TWFE regression with an M2 outcome variable results in divergent asymptotic behavior and there is little test power to detect policy impacts. Taking first-differences can alleviate the lack of power that affects TWFE regression when the DGP of y_{it} contains linear trends. But TWFE regressions formulated with first differenced outcomes are not suited to evaluate the effectiveness of policy changes if y_{it} involves non-linear trend effects. In such circumstances the problem of how to evaluate the effectiveness of policy changes is of considerable empirical interest. Two solutions are discussed in the next section.

Figure 2: Data Generating Process and Observed Series

Notes: y_t is the cross-sectional average of the log cumulative vaccination rates for states initially in 'club 2', the states with the relatively low initial cumulative vaccination rates. These states were impacted by the FEVM, which caused the slope of their relatively low cumulative vaccination rates to increase. x_t is the FEVM, and we decompose $\tilde{y}_t = y_t - T^{-1}$ as $\sum_{t=1}^T = b_t \theta_t$ where $b_t = x_t$. Having assumed this relationship we calculate the unknown trend, θ_t , by dividing \tilde{y}_t by b_t . Thus, x_t has a one to one relationship with b_t . Figure 2(a) displays the FEVM variable, x_t and the calculated hypothetical trend variable, θ_t . The figure clearly shows the nonstationary nature of the θ_t . Figure 2(b) plots the mean cumulative vaccinations, y_t alongside x_t . The two are clearly positively correlated, but due to the nonstationary and nonlinear trending nature of y_t , this relationship is not stable in the long run, as discussed in subsection 2.1. Figure 2(c) displays the FEVM and the first-differenced average log cumulative vaccination rate, Δy_t . The pitfalls discussed in subsection 2.2 are readily apparent in this figure, as there is a clear negative relationship between the FEVM and Δy_t even though θ_t is generated using $x_t = b_t$.

3 A Dynamic Clustering Approach

This section describes a clustering approach to the evaluation of policy impacts in the presence of trending outcomes. The first part introduces the relative convergence test proposed by P-S, which can be used to test for a common nonlinear or stochastic trend in outcome data. If a panel of interest shares a common nonlinear or stochastic trend, then the TWFE regression in (16) is valid since x_{it} cannot influence the homogeneous trend coefficient heterogeneously.¹² The second part provides a methodology for transforming nonstationary panel data into stable multinomial club membership using a recursive clustering algorithm.

¹²Identification of the long run determinant then becomes of interest because in this case x_{it} does not affect the long run trend of y_{it} . Analysis of this case is a separate matter and left for future research.

3.1 Testing for Homogeneous Trends

As in P-S, the starting point is to represent trending multidimensional data in terms of a panel components model as

$$y_{it} = b_{it}\theta_t, (20)$$

where θ_t is an unknown trend which may be either a stochastic process or a nonlinear deterministic time trend. The representation in (20) is general and typically has unidentified multiple components. For instance, if the DGP were $y_{it} = a_i + b_i t + \xi_{it}$ where $\xi_{it} = \xi_{it-1} + e_{it}$, then we could rewrite the model in the form of (20) as $y_{it} = (a_i t^{-1} + b_i + \xi_{it} t^{-1})t = b_{it}t$.

If $y_{it}/y_{jt} \to 1$ as $t \to \infty$, then we say that y_{it} relatively converges to y_{jt} over time. Let $\hat{\mu}_t$ be the sample cross section average of the y_{it} . If $y_{it}/\hat{\mu}_t \to 1$ as $t \to \infty$ for all i, then the panel y_{it} is said to be relatively convergent to its cross section average. The ratio $h_{it} := y_{it}/\hat{\mu}_t$ traces out a transition path over time that manifests convergence when $h_{it} \to 1$. In this case, y_{it} shares the same (stochastic) trend, which is factored out in the ratio, thereby enabling analysis and inference about convergence. Figure 3 shows the relative transition paths for two groups in our empirical

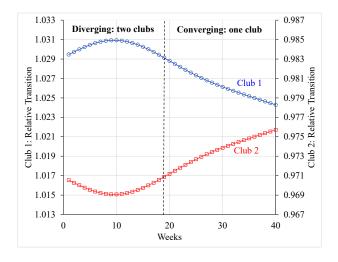

Figure 3: Relative Transitions for Club 1 and 2

Notes: The blue line with circles is the relative transition path of states that were initially in Club 1, where the Club 1 relative transition path is defined as the ratio of the average cumulative vaccination rate of states in Club 1 (C_1) at time t, divided by the national average cumulative vaccination rate at time t, $\frac{1}{n_1}\sum_{i=C_1}^{n_1}\frac{y_{it}}{\mu_t}$. Similarly, the relative transition path of Club 2 (C_2), $\frac{1}{n_2}\sum_{i=C_2}^{n_2}\frac{y_{it}}{\mu_t}$, displayed in red with squares, charts the ratio of the average vaccination rate of states belonging to Club 2 to the national average. As the figure shows, initially the ratio of Club 1 vaccination rates to the national average was increasing, meaning that the states in Club 1 had cumulative vaccination rates that were increasing relatively faster than the national average. Necessarily, this means that the vaccination rates in Club 2 were increasing relatively slower than the national average. This trend continued through week 10, at which point the largest distance between the relative transition paths of Club 1 and Club 2 was reached. From weeks 10 onwards the distance between the two paths decreases indicating convergence to a single club toward the end of the period.

example. 'Club 1' and 'Club 2' are the cross-sectional averages of the relative transition curves for high and low vaccination states, respectively. In this case there was no overall convergence early in the period, as evident in the initially diverging paths of the two clubs. If there were initial convergence, we would have only a single club and the ratios would converge with $\frac{y_{it}}{\mu_t} \to 1$ for all

states i. Instead, up until the 10th week the distance between two clubs increased, showing clear evidence of divergence. Following the 10th week the distance between them decreases but remains larger than the initial distance for the next week. But after the 19th week, the distance between the two groups continues to decrease and is soon less than the original distance, suggesting a merger of the two clubs to a larger single convergence club.

The test for relative convergence in P-S relies on the following (so-called $\log t$) regression

$$\log \frac{H_1}{H_t} - 2\log(L(t)) = a + b\log t + e_t, \tag{21}$$

which is estimated by ordinary least squares and where

$$H_t = \frac{1}{n} \sum_{i=1}^{n} (h_{it} - 1)^2$$
, for $h_{it} = \frac{y_{it}}{\hat{\mu}_t}$, (22)

 $L(t) = \log t, t = p + 1, \dots, T, p = \lfloor r \times T \rfloor$ with r = 1/3, and $\lfloor \cdot \rfloor$ is the integer floor function.

Under the null of relative convergence, H_t is asymptotically convergent to zero over time since $h_{it} \to 1$ as $t \to \infty$. Hence, $\log(H_1/H_t)$ is increasing over time. If the t-value for \hat{b} exceeds -1.65, then the null of relative convergence is not rejected in the test at the 5% level. Note that in finite samples the term involving $2 \log(L(t))$ serves as a penalty function in the regression (21), as explained in P-S. Under relative divergence, H_t and $\log(H_1/H_t)$ should increase and decrease over time, respectively. Under fluctuations over time, H_t simply fluctuates, but in view of the penalty function of $-2 \log(L(t))$, the dependent variable in (21) decreases over time. Hence, the fitted OLS coefficient \hat{b} becomes significantly less than zero in this case.

For present purposes in the empirical evaluation of policy effects under trending outcomes, if the null of convergence is not rejected, then the TWFE regression with Δy_{it} is well justified since in the long run the panel y_{it} is identified as having a homogeneous (stochastic or nonlinear) trend. If the null is rejected, then data analysis may be conducted as described in the next section.

3.2 Dynamic Clustering Mechanism

One possible outcome is that there are few sub-group convergences, but each of these clubs diverges from the others over time, in which case a null of overall club convergence would be rejected. P-S suggested how to find convergent sub-groups by using an convergence clustering mechanism (CCM). This mechanism transforms the full $(n \times T)$ panel dataset into a club membership structure that features each individual member $(n \times 1)$. The CCM requires finding a core convergence club within the panel. Once a core club is identified, each individual time series is compared with the core group and is added to the convergence group if it relatively converges. Otherwise, the individual is classified to another group. Successive repetition of this procedure identifies members of the

first convergent club. The clustering algorithm is then repeated with non-members of the first convergent club. The approach allows empirical researchers to explore the underlying determinants of club membership through multinomial logit regression of club membership on driver variables, as suggested in Phillips and Sul (2007b) and Phillips and Sul (2009).¹³

$$y_{it} \sim I(1) \rightarrow \boxed{CCM} \rightarrow C_i$$

The present paper utilizes this approach to design a robust method of clustering club membership over time. The proposed method is straightforward and involves recursive implementation of the CCM algorithm over time to identify the clusters and cluster evolution over time. As we will show in the next section, various patterns of dynamic evolution over time can be identified by recursively estimating club memberships in this way.

This dynamic version of the CCM (DCCM) approach transforms nonstationary y_{it} to stationary panel ordered variables, i.e.,

$$y_{it} \sim I(1) \rightarrow \boxed{DCCM} \rightarrow C_{it} \sim I(0).$$

The DCCM employs some modifications of the original algorithm including a fixed rule for initialization in the recursive regressions ¹⁴ and a fixed rule for core member detection. ¹⁵

The asymptotic justification for the clustering method is given in Appendix C of P-S. As long as the number of core members is not large relative to the time series sample, consistency of the clustering mechanism is easily achieved. Consistency of the dynamic version of the CCM approach can be achieved in the same way. The online supplementary appendix provides details of this method and reports findings of its finite sample performance from Monte Carlo simulations.

If we knew the specific functional form of dependence and values of b_{it} it would be straightforward to evaluate its determinants by running a regression of b_{it} on the relevant function $f(z_i, \theta_{x,t}, x_{it})$. In practice, finding a specific functional form is challenging and consistent estimation of all of the idiosyncratic trend coefficients b_{it} is not possible using only the data y_{it} . To avoid these issues, we utilize the clustering method in P-S, as now explained.

¹³See Sul (2019) for more detailed discussion.

 $^{^{14}}$ The log t test in P-S requires initialization of the regressions, eliminating some early observations. The discard rule in P-S removed the first 1/3 observations. This rule is problematic in the present implementation because the sample size changes in recursive regression. Instead, a fixed rule is used here in which the first 5 or 6 observations are discarded. The Online Supplement provides further discussion.

¹⁵The CCM algorithm estimates the initial core members based on the sample observations. To maintain the core membership in the recursive approach, the core members are fixed in the recursion by employing the entire sample in their initial detection.

¹⁶P-S simplifies this challenge by approximating b_{it} using a relative transition curve h_{it} as explained earlier in (22). However, in this approach the sample cross-sectional mean is often not a robust measure and can be sensitive to outliers, so it is not used here.

Define J as the number of convergent sub-groups: $j=1,\dots,J$. The original algorithm was designed to provide club memberships based on descending order of the final observation values, y_{iT} . Hence, the first convergent sub-group always dominates the remaining convergent sub-groups. Define \hat{C}_{it} as the estimated membership emerging from the application of dynamic CCM for the ith individual from 1 to ith transformation changes nonstationary outcomes y_{it} to stationary club memberships, \hat{C}_{it} .

3.3 Panel Ordered or Logit Regression

If the membership does not change over time, one does not need to run panel ordered logit, but simply run an ordered logit regression with the final club memberships at time T. Otherwise, the next panel ordered logit regression can be run. The j-th ordered logit model is given by

$$\operatorname{Prob}(\hat{C}_{it} > j) = \frac{\exp(a_j + z_i' \gamma_j + \theta_{x,t}' \lambda_j + x_{it}' \beta_j)}{1 + \left[\exp(a_j + z_i' \gamma_j + \theta_{x,t}' \lambda_j + x_{it}' \beta_j)\right]}, \text{ for } j = 1, \dots, J - 1,$$
(23)

where $\theta_{x,t}$ is a vector of known common policy variables, such as macro factors including market interest and inflation rates, and federal policy changes. Once the known common factors are included in the regression, panel fixed effects cannot be identified.¹⁷ Note that all variables on the right hand side influence the trend coefficients in y_{it} . Variables not affecting the trend behaviors of y_{it} must not be significantly different from zero.

In the case of two sub-convergent clubs, as is the case in the empirical study of the next section, instead of a panel ordered logit regression one needs to run a panel logit regression with random effects. In this case, $\hat{C}_{it} = 1$ or 0, and the ordered logit regression becomes

$$\hat{C}_{it} = 1\{a + z_i'\gamma + \theta_{x,t}'\lambda + x_{it}'\beta + e_{it} \ge 0\},\tag{24}$$

Note that neither conditional logit nor ordered logit regressions can identify λ since $\theta_{x,t}$ is common across individuals so that the conditional likelihood function eliminates $\theta'_{x,t}\lambda$ automatically.¹⁷

The economic interpretation of β in (23) and (24) is different from that of conventional TWFE regression. Since the dependent variable is club membership, the marginal effect of x_{it} is of interest, which indicates the change in probability when x_{it} increases by one unit. The unconditional logit regression in (24) also provides potentially complex causal effects to explain club membership. To see this, rewrite (24) with a single variable, ignoring x_{it} and e_{it} . Further, let $\gamma = \lambda = 1$ and a = 0. If the *i*-th state is in the first convergent sub-group at time t, then assign $\hat{C}_{it} = 1$; if it

The conditional probability at time t=1 becomes $\frac{\exp(\lambda\theta_{x,1}+\beta x_{11})}{\exp(\lambda\theta_{x,1}+\beta x_{11})+\exp(\lambda\theta_{x,1}+\beta x_{21})}=\frac{\exp(\beta x_{11})}{\exp(\beta x_{11})+\exp(\beta x_{21})}$. So λ cannot be identified with observed $\theta_{x,t}$.

is in the second convergent sub-group, then assign $C_{it} = 0$. Assume that $\theta_{x,t}$ is a federal policy which implements after $t \geq \tau$ (so $\theta_{x,t} = 0$ if $t \leq \tau$, otherwise $\theta_{x,t} = 1$), and z_i is a particular state characteristic variable. Then, depending on the values of z_i , the federal policy may influence the club membership differently.

Importantly, the proposed methodology is designed to identify determinants of club memberships rather than estimate overall treatment effects. If y_{it} includes a nonlinear trend and exogenous policy variables cause changes in the trend behavior, the proposed method can identify the relevant exogenous variables but not estimate the overall treatment effects on y_{it} . But it is possible to deduce relative information about the implied treatment effects. For instance, take the case of two convergence sub-groups and define $n_{\mathcal{G}_{a,t}}$ as the number of individuals in \mathcal{G}_a at time t for $a \in \{1, 2\}$. Then the average outcomes for each sub-group can be estimated directly from the data by

$$\hat{\mu}_{\mathcal{G}_1} = \frac{1}{n_{\mathcal{G}_{1,t}}} \sum_{i \in \mathcal{G}_1} \frac{1}{T - \tau_i - 1} \sum_{t > \tau_i, \hat{C}_{it} = 1}^T y_{it}, \tag{25}$$

$$\hat{\mu}_{\mathcal{G}_2} = \frac{1}{n_{\mathcal{G}_{2,t}}} \sum_{i \in \mathcal{G}_2} \frac{1}{T - \tau_i - 1} \sum_{t > \tau_i, \hat{C}_{i,t} = 2}^T y_{it}.$$
(26)

The difference between these two averages provides an estimate of the difference between the two average overall outcomes, thereby giving information about the relative impact of the two treatments. If these two convergence sub-groups eventually merge into a single convergence group from some point $t \geq \tau$, then it is known that the treatment outcomes effectively become the same from this point.

We note finally that in any convergence sub-group empirical analysis some individuals may end up outside any of the identified groups. Such individuals are treated in P-S as outliers or divergent members of the population. In this case the relevant individuals display behavior outside the framework of the convergence analysis and these outcomes may need separate empirical study to explain their behavior.

4 COVID-19 Vaccination in the US

As an empirical illustration, our recursive club clustering methodology was applied to state-level COVID-19 vaccination rates in the US and panel logit regressions were employed to explore the impact of vaccination policies on actual vaccination rates. By late spring of 2021 COVID-19 vaccinations were widely available in the US, but vaccination rates began to plateau even though

only roughly 45% of the targeted US population were fully vaccinated by mid-May 2021. There was also substantial variation in state vaccination rates: Maine had the highest vaccination rate at 49% in mid-May 2021; and Mississippi had the lowest at the time, with only 26% of residents fully vaccinated.

Determinants of this variation in state vaccination rates are naturally of considerable interest to policy makers, epidemiologists, and social scientists. Some preliminary research conducted over the summer of 2021 pointed to partisanship having a strong association with vaccination rates. Specifically, it was found that the percentage of votes cast for Donald Trump in the 2020 presidential election was a primary predictor of vaccination rates: the higher the Trump vote, the lower the vaccination rate, on average. Around the same time in 2021, cities, counties, and states attempted to bolster their waning vaccination rates by implementing various vaccine incentive campaigns such as vaccine lotteries and cash for vaccination. Numerous studies have examined the efficacy of such incentives in various states and counties across the United States, and have come to differing conclusions. Some found modest increases in vaccinations resulting from vaccine lotteries or cash incentives, while others found no statistical evidence that these lotteries or cash incentives increased vaccinations, even finding small negative impacts in some cases. Table 2 provides reference details for some of these explicit findings in the literature.

Table 2: Findings of Vaccination Incentives

Small Positive Effect	Zero or Small Negative Effect			
Barber and West (2022)	Chang et al. (2021)			
Brehm et al. (2022)	Dave et al. (2021)			
Sehgal (2021)	Lang et al. (2022)			
Wong et al. (2022)	Thirumurthy et al. (2022)			
	Walkey et al. (2021)			

By late summer 2021, policies mandating vaccinations for particular sub-populations were being announced and implemented at the state and the federal level. To examine the impact of vaccination incentives and policies on vaccination rates, we assembled a dataset of vaccination policies and incentives at the state level, including policies that were implemented in large cities or counties within a state. Appendix A explains how the state policy dataset was constructed and appendix table 6.1 provides summary statistics for the various state-level policies.

In addition, we created a separate federal-level vaccine mandate variable. This variable includes information from a combination of vaccine mandate announcements that were national in scale.

 $^{^{18}}$ The term fully vaccinated was defined at the time as two doses of the Pfizer or Moderna vaccine, or a single dose of the Johnson & Johnson vaccine.

More specifically, it includes the military vaccine mandate, the various vaccine mandates announced by President Biden on September 9, 2021¹⁹, and mandates by private employers that typically were national in scope. Details on the construction of the federal vaccine mandate variable are given in Appendix B, and appendix table 6.2 displays the relevant events and dates that were used.

Our state-level vaccination data came from the publicly available county-level data from the Centers for Disease Control and Prevention (CDC), spanning the period from December 13, 2020 to February 9, 2022. Data prior to May 12, 2021 was discarded because COVID vaccines were initially in short supply and difficult to obtain, meaning that discrepancies in vaccination rates across states during this early period may not have been voluntary but simply due to availability. By mid-May 2021 Covid-19 vaccines were easily accessible in most areas of the United States. Daily county-level data were converted to weekly state-level data and logarithms of the resulting vaccination rates were recorded. There were a few points of decreasing cumulative vaccination rates for a short period in a small number of states in the data, which was likely due to state or county reporting errors. To correct for these, we applied Stata's HP filter²⁰ with a smoothing parameter of 1600,²¹ and then subtracted y_{min} , as suggested in Section 3.1 of the Online Supplement.

As Figure 4 shows, the implementation percentages of both federal-level mandates, and state-level mandates are very low through late July 2021, at which point they both sharply increase and then stabilize. State vaccination mandates stabilize around 0.45, meaning about 45% of states had some form of state-level vaccination mandate in place by September 2021. Federal vaccine mandates sharply increase over roughly the same time period, although the increase is more stairways than a single sharp jump, as is the case with state-level mandates. The federal-level mandates level off at an implementation rate of 100% since all states were impacted by this federal-level mandate. Vaccination lotteries also show a sharp increase, but the increase is several weeks earlier than the vaccine mandate increases. This shows that states initially tried to incentivize people to get vaccinated through positive incentives. After peaking in June of 2021, the use of lotteries to incentivize vaccination started to steadily fall away until converging at zero.

Cumulative vaccination rates are partial sum time series and therefore typically stochastically nonstationary. For the reasons explained earlier involving the effects of regression imbalance, these characteristics suggest caution in the use of random effects or fixed effects linear regression to

¹⁹Not all of the federal mandates announced by President Biden on September 9, 2021 were ultimately implemented. The mandate on large employers was struck down in court, and the mandate for employees of federal contractors was blocked for months before an August 31, 2022 announcement from the federal government that it would not be enforcing the mandate.

²⁰The HP filter is by far the most commonly used filter in empirical studies that have employed the P-S CCM algorithm. We considered other filters in the empirical application with little changes in the results.

²¹Since the data are weekly, higher values than the quarterly smoothing parameter 1600 are sometimes preferred. In the present case our goal is to smooth the series only moderately because use of a smoothing parameter that is too large produces a filtered trend that is almost linear. Provided the smoothing parameter is neither very small nor very large, the empirical results were not sensitive to the specific choice. Details are provided in the online supplement.

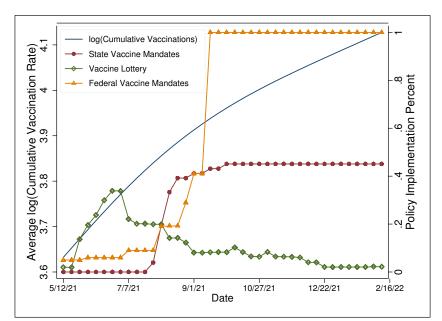

Figure 4: log(Cumulative Vaccination Rate) and Select Policy Common Trends.

Notes: The left vertical axis scale is the logarithm of the national average cumulative vaccination rate, which corresponds with the smooth blue line. The right vertical axis scale is the adoption percentage of vaccination policies. The maroon, green, and orange lines are measured on the right axis, and each is the national average of the policy at each time t. The maroon and green lines are sample state-level vaccination policies, vaccine mandates for state employees and/or healthcare workers, and vaccination lotteries, respectively. The orange line is federal-level vaccine mandates. Log cumulative vaccinations do not show any jump or discontinuity over time and the path of this variable appears impervious to the policy variables being enacted.

assess the impact of vaccination policies on cumulative vaccination rates. Using first differences (new vaccination numbers) as the dependent variable does not resolve the imbalance when the data involve non-linear heterogeneous trends; and first difference specifications are less helpful in addressing the primary issue of modeling discrepancies in overall state vaccination rates.

To address heterogeneity and nonlinearity in the trend behavior of the data our empirical approach is to classify state vaccination rates into groups where homogeneous trends are manifest. The groupings were obtained by applying the P-S automatic clustering technique to log cumulative vaccination rates, y_{it} , producing individual club membership data \hat{C}_{it} , which is the estimated convergence club that state i belongs to at time t. As previously noted, \hat{C}_{it} takes on the value of 0 or 1 when there are two convergence clubs. Also, as noted earlier, when vaccination rates began to plateau in each state a variety of vaccination incentive schemes and policies were announced and implemented. Examining club membership data at a single fixed point in time does not reveal the dynamic effects on club membership over time as these policies were rolled out. To explore the evolutionary relationship between club membership and individual state policy implementation we employed the dynamic club clustering technique described earlier in Section 3.

We first applied the automatic clustering mechanism on the full data set from May 12, 2021 to February 9, 2022, using m=6, where m is the first sample observation used in the regression, a setting that matches findings from the simulations reported in Section 4 of the Online Supplement. The t-ratio from the initial $\log t$ regression of the entire data set was 7.24, so that the null of convergence was not rejected, implying that vaccination rates of all fifty states plus the District of Columbia were converging to the same long run national average in February, 2022. Implementation of the P-S clustering algorithm produced a core group of eight members: Connecticut, the District of Columbia, Maine, Maryland, Massachusetts, New York, Rhode Island, and Vermont. This club membership outcome is a static full sample result that is uninformative regarding the actual process of convergence and, in particular, the important empirical question of whether state convergence may have occurred without intervention or whether vaccination policies impacted state convergence over time.

To address this question dynamic clustering was employed with recursive sampling to estimate club membership evolution over time. Core membership was fixed to the aforementioned seven states plus the District of Columbia. From this core membership we applied the remaining steps of the clustering process using the first thirteen weeks of data from May 12, 2021 to August 4, 2021. Interestingly, with this shortened dataset involving vaccination rates only from the late spring to the mid-summer of 2021, there was no evidence of convergence to a single long run average. Instead, during the summer of 2021 there were two distinct clubs: one comprising thirteen members (twelve states plus the District of Columbia) with relatively high vaccination rates, and a second club consisting of 38 states with relatively low vaccination rates.

Working from the given initial club membership obtained for the original (May 12 - August 4) sample, a recursive analysis was commenced by adding a further week to the original sample, giving the new sample span from May 12, 2021 to August 11, 2021. The clustering algorithm was re-applied, using the same fixed core. This resulting outcome again produced two clubs, but Club 1 had all original thirteen members in the higher vaccination group that were in the May 12, 2021 - August 4, 2021 sample plus two additional states. This process was continued adding one week at a time and re-running the club clustering process to the end of the sample. With the addition of each additional week to the sample, the outcome produced more states joining the relatively high vaccination club, Club 1, each week. This pattern continued until the sample included data from May 12, 2021 - September 1, 2021. At this point, all of the states had relatively converged, forming a single convergence club. Relative convergence to a single club continued to hold for each additional week included until the recursion covered the entire sample, May 12, 2021 to February 9, 2022.

Figure 5 shows the dynamic membership evolution of Club 1 from May 12 through September 1, 2021. The top left panel shows the twelve states plus the District of Columbia in Club 1 from May 12, 2021 - August, 2021. Each subsequent panel shows the states belonging to Club 1 as

the sample recursively expands. Club 1 membership evidently grows over time, as expected from Figure ??. The last panel, in the lower left position, shows that when the dataset includes weeks from May 12, 2021 through September 1, 2021, all the US states are seen to have the same club membership and full convergence applies.

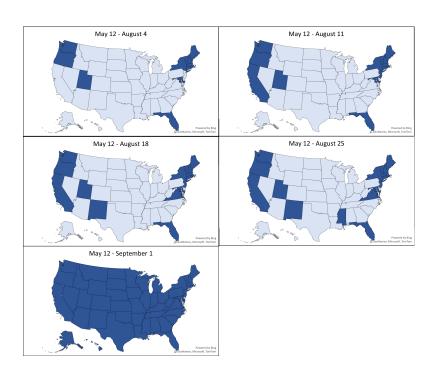

Figure 5: Dynamic State Membership in Club 1

Notes: The states shaded dark blue are in Club 1 and the light blue states are in Club 2. As the sample added weeks the membership of Club 1 continued to grow until September 1, 2021, at which point Club 1 included all states giving a single convergence club.

Figure 6 shows federal-level vaccine mandate variables plotted alongside the evolving Club 1 membership. Two federal-level vaccine mandate variables are displayed in the graph: one includes private employer vaccine mandates and the other does not. By design the fraction of states in Club 1 held constant through to August 4, at which point it began to rise steadily for several weeks merging into a single convergence club in September. The federal-level vaccine mandates started to increase slowly at first over May-July and subsequently rose rapidly through to September, at which time President Biden announced four federal-level mandates estimated to impact 100 million American workers. The fraction of state membership of Club 1 closely tracks the course of these federal-level mandates.

The federal mandates variable, the state policy dataset, and the dynamics of club membership offer the opportunity to explore the impact of federal-level mandate announcements and state-level

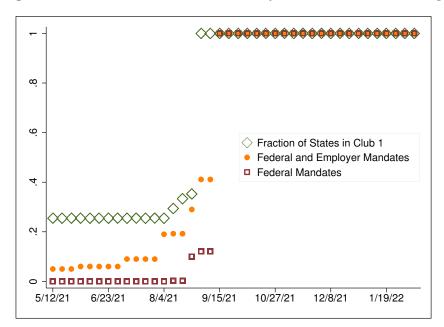

Figure 6: National-Level Mandates and Dynamic Club 1 Membership

Notes: The federal mandates variable is plotted in maroon, this variable combined with employer mandated vaccinations is plotted in orange, and the fraction of states belonging to Club 1 is plotted in green. The fraction of states in Club 1 and the federal vaccine mandate variable are flat until early August 2021. The federal mandates variable, the one capturing both the federal mandates and the employer mandates, slowly increased in early summer 2021 before increasing dramatically from July to August 2021, and again from August to September 2021. All three variables end up at unity by September 9, 2021.

policies on club membership. An unconditional panel logit (random effects) regression in (24) was used to examine some of the effects of these time-varying policies. We used the combined federal and employer mandates as a common factor θ_t , and various state specific variables as z_i including political trends, state demographic characteristics, such as population density, median household income, and education, and the percentage of people employed by industry for each state. Various state-level vaccination policy variables comprise x_{it} , including state incentives for vaccinations and state vaccination policies.

Table 3 column (5) shows the results of the preferred specification from the panel unconditional logit (random effects) regressions.²² The large coefficient on the federal-level mandate variable shows that the probability of being in Club 1 given the federal-level mandate is extremely high.²³ This matches Figure 6 where transition to Club 1 moves very closely with the implementation of the federal-level mandates. Interestingly, no state-level vaccination policies or incentives had any significant impact on club membership. Also, contrary to our findings in the summer of 2021,

²²Table 9 in the online supplement reports results of other specifications used in the unconditional panel logit regressions.

²³We also ran the model for column (5) from Table 3 with a two-week lag in each of the policy variables. Including the two-week lag did not impact the findings. See Table 10 in the Online Supplement.

by February 2022 our results suggest that once population density, median household income, the percentage of the population that is foreign-born, and the industry composition of a state are all controlled for, political party is not associated with club membership in a statistically significant way. States with a larger percent of foreign born individuals were more likely to be in Club 1 initially. States with higher numbers of health care and social assistance workers as well as higher percentages of people employed in the retail trade industry were also initially more likely to be in Club 1, whereas states with higher percentages of employees working in wholesale trades were less likely to be in Club 1. The McFadden pseudo R^2 value is very high for our preferred specification, showing that the improvement in our model from the based intercept only specification is substantial, indicating the fitted model regression almost fully explains club membership.

For comparison with the above findings linear random effects regressions were run according to the following specifications using levels and differences as the dependent variable:

$$y_{it} = a + z_i' \gamma + \lambda \theta_t + x_{it}' \beta + \epsilon_{it}, \tag{27}$$

$$\Delta y_{it} = a + z_i' \gamma + \lambda \theta_t + x_{it}' \beta + \epsilon_{it}, \tag{28}$$

$$y_{it} = a_i + \lambda \theta_t + x'_{it}\beta + \epsilon_{it}, \tag{29}$$

$$\Delta y_{it} = a_i + \lambda \theta_t + x'_{it} \beta + \epsilon_{it}, \tag{30}$$

where y_{it} is the logarithm of state i's cumulative vaccination rate, Δy_{it} is the log of the number of new vaccinations per 10,000 people (the first difference of vaccinations), θ_t is the federal-level mandates, z_i are state fixed effects, and x_{it} is a vector of state-level policies and the number of new infections per 10,000 people in a state each week. The results are displayed in columns 1-4 of Table 3. The R^2 values show that the policies explain significantly more of the variation in cumulative vaccination rates than they do new vaccinations. The coefficients and levels of significance are very similar to the random effects model and fixed effects model for each of the dependent variables. For this reason we limit our discussion of the regression results here to the fixed effects model for both dependent variables.

When the log cumulative vaccination rate is the dependent variable, new infections and federallevel vaccine mandates are both positive and highly significant. But, state-level policies have no significant impact on cumulative vaccinations, with the exception of bans on proof of vaccination. That positive coefficient result suggests that if a state implemented a ban on proof of vaccination, cumulative vaccinations in that state would increase, which is a curious outcome that may be the spurious result of the nonlinear trend effects discussed earlier.

In the regressions with new (first differenced) vaccinations as the dependent variable there are several anomalous signs in the fitted coefficients. For instance, the signs on new infections,

Notes: Numbers in parentheses are standard errors. Median household income is measured in tens of thousands of dollars and population density is per 1,000 square miles. The dependent variable for the linear level model, y_{it} , is log(cumulative vaccination rate) and the dependent variable for the linear first-differenced model, Δy_{it} , is log(new vaccinations per 10,000 people). The binary club membership obtained from the P-S club clustering technique, \hat{C}_{it} , is the dependent variable in the logit regressions. The coefficient on the federal-level mandates in the unconditional logit model is large and all state level policies had no impact on the likelihood of being in the high vaccination club.

federal-level vaccine mandates, and state-level mandates on state employees are all negative and counter-intuitive as higher infection rates and vaccination mandates are more likely to increase than reduce new vaccinations. Further, the empirical results imply that the only state-level policy that increased new vaccinations per 10,000 people was a ban on mask mandates. It might be argued that banning mask mandates led people with high risk aversion to Covid-19 infection to get vaccinated because they felt less secure, but those people were already most likely to be vaccinated. As discussed earlier in Section 3, use of first differences does not eliminate time trend effects in the data and these counter-intuitive results are again the likely outcome of misspecification and failure to capture separate group behavior in the data.

In sum, comparing the regressions results across Table 3, the panel logit regressions seem to provide the most plausible and intuitive findings. The natural explanation is that the panel logit models provide well specified formulations that take account of club membership arising from nonlinear trend effects and separate group convergence behavior that together determine cumulative vaccinations.

5 Conclusion

When outcome variables have nonlinear and possibly stochastic trends, evaluating the effectiveness of policy changes by using TWFE regressions can be problematic. This paper shows the underlying reasons for this empirical problem and proposes an alternative approach. The key idea is a simple method to transform panel nonstationary outcome data into panel multinomial data by using a dynamic clustering method based on the relative convergence test of Phillips and Sul (2007a). This approach allows researchers to use panel logit regressions to investigate how policies that are implemented can impact convergence club membership or the long run behavior of the dependent variables over time.

The dynamic convergence clustering mechanism is applied to state-level Covid-19 vaccination rates in an empirical example of this methodology. Our findings indicate that there were initially two distinct convergence clubs, but over time all states converged to a single club. Finally, we use panel logit to show how national and state policies impacted club membership over time, and we demonstrate how the regression results from panel logit regressions appear to give more realistic results than linear models.

There are two drawbacks of the proposed method. First, the number of time series observations cannot be too small. To estimate time varying convergent club membership the time series sample size T should be large enough to capture the evolution of club membership. In the Covid-19 vaccination empirical example T=40 observations were available for the time series sample and the recursive sampling procedure was initiated with sample size T=13. This choice complies with the minimum sample size T=10 for the clustering algorithm that was used in Phillips and Sul

(2007a). When T is smaller we suggest not using the dynamic CCM but instead static CCM and running a cross-sectional logit or multinomial logit regression.

Second, to use the proposed method, the panel should be balanced since the dynamic CCM tracks each individual club membership over time. If some data are missing within time periods, then interpolation and filtering to smooth out the series can be employed. Since the proposed method is designed for analyzing long run effects, small modifications of this type typically do not affect the membership findings. If data are missing at the beginning or end of the sample, then backward or forward forecasting would be required and the accuracy of such modifications is not studied in the paper.

6 Appendix

6.1 Appendix A: State Policy Variables

We created a database that tracked state (and District of Columbia) announcements of vaccination lotteries, cash for vaccination incentives, community outreach programs, vaccine mandates for state employees and or healthcare workers, indoor vaccine mandates or mandates for gatherings over a certain number of people, mask mandates, bans on proof of vaccination, and bans on mask mandates. (Only mask mandates that were re-implemented after June of 2021 were included since virtually every state had some form of mask mandate at the beginning of the pandemic.) This database is weekly and tracks policies from March 2021 to February 2022. The policies are tracked from the date of their announcement. We also included polices that were implemented by large cities or counties since it was occasionally the case that a large city or county would implement a policy which impacted many people in a state, but the policy was not implemented at the state level. Chicago, for example, gave cash incentives for vaccination, but the state of Illinois did not. The population of Chicago makes up 20.9 percent of the population of Illinois, so for the weeks that Chicago offered cash incentives, we populated the cash field for Illinois in the dataset with a value of .209 rather than 1. We went state by state and gathered information about policies that were implemented and the timing of the policies. We found policy data from AARP (formally the American Association of Retired Persons), The National Governor's Association, Becker Hospital Report, The Rockefeller Foundation, The Kaiser Family Foundation, Ballotpedia, and various other websites. We also made a list of the two largest counties and cities in each state and used Google to search for any policies implemented in those localities. Any other local policies in cities or counties other than the two largest in each state that came up in our Google searches were included (as their percentage of state population) if the locality made up at least two percent of the state population.

Appendix Table 6.1: Summary Statistics for State Vaccination Policies

	Lottery	Cash	Com Out	VMSE	IVM	MM	BPV	BMM
Mean	0.108	0.067	0.053	0.301	0.050	0.170	0.388	0.190
Cross Section Median	0.025	0.004	0.000	0.000	0.000	0.028	0.000	0.000
Overall Median	0.000	0.000	0.000	0.000	0.000	0.000	0.000	0.000
Cross Section Variance	0.022	0.013	0.087	0.112	0.019	0.072	0.218	0.149
Overall Variance	0.094	0.050	0.127	0.211	0.040	0.122	0.238	0.154
Number of States	33	29	16	23	11	33	21	10

Notes: The number of states listed in the final row is the total number of states that implemented the policy at some point. If a large locality within the state implemented the policy, that is included in the state count. Cross sectional median is the median of the time series mean of each state. Cross section variance is the variance of the time series mean of each state. All variables were tracked from their announcement date. Some policies were challenged legally, but were still tracked from the date of their announcement. Com Out: Community Outreach, VMSE: Vaccine mandate for state employees and/or health care workers in a state, IVM: Indoor vaccine mandate or vaccine mandate for gatherings over a certain size, BPV: Ban on requiring proof of vaccination, BMM: Ban on mask mandates.

6.2 Appendix B: Federal Policy Variables

On September 9, 2021 President Biden announced vaccine mandates that would be rolled out over the next several months. The mandates applied to most federal employees, employees of federal contractors, medical workers who worked at facilities that accepted Medicare and Medicaid reimbursement, and employers with 100 or more employees. It was estimated that the mandates would apply to roughly 100 million US workers. Rather than use a binary indicator variable for federal vaccine mandates, equal to zero before and unity after September 9, we created a linearly interpolated variable that captured the increase in federal-level vaccination mandates during the time period. Prior to President Biden's September 9th announcement, a mandate on members of the military was already in place, and hundreds of employers (many of them with employees nationwide) in the United States chose privately to have their own employer vaccination requirements. In order to fully capture mandates at the federal-level we felt it important to include employer mandates that impacted workers nationwide.

To quantify how many employees were under employer mandates, we used a Gallup poll that was taken monthly from May through December 2021. (Jones, 2021) The poll asked workers to the best of their knowledge whether their employer would require vaccination against COVID-19. In May of 2021 only five percent of employees said their employers mandated vaccination. By October 2021, just five months later, that number increased to 36 percent of workers that had employer mandated vaccination. We combined the employer mandated percentages with the military and federal vaccine mandates to construct the federal-level vaccine mandate variable. We also took into account announcements made by the Secretary of Defense and the White House that signaled that vaccine mandates were likely to come in the near future. Appendix Table B shows the dates that

were used to construct the federal vaccine mandate variable as well as the combined federal and employer mandates variable.

We included the signals of future mandates because of those who were eligible for vaccination by the summer of 2021, but who were still not vaccinated, there were two groups. The first group consisted of those who were vaccine hesitant and wanted to wait for full Food and Drug Administration (FDA) approval of the vaccines, or planned to get vaccinated and just hadn't gotten around to it yet. The other group was the vaccine resistant who were opposed to the vaccine at almost any cost and were willing to suffer the consequences of not being vaccinated if mandates were enacted. Vaccine mandates, whether federal or at the employer level, did not likely increase vaccines among the latter group in a significant way. The former group, however, were likely influenced by such mandates, and the mere announcement of the mandates were sufficient to nudge them into action and get vaccinated. (The Pfizer vaccine also was granted full FDA approval during this same time period, on August 23, 2021.)

Appendix Table 6.2: Federal and Employer Vaccine Mandates and Club 1 Membership Size

Date	Federal and Employer Mandates	Members in C1
May 2021	5% of employees report having employer vaccine mandate	13
June 2021	6% of employees report having employer vaccine mandate	13
July 2021	9% of employees report having employer vaccine mandate	13
$\mathrm{Aug}\ 9,\ 2021$	Secretary of Defense sent message of intent to mandate	13
	COVID-19 vaccination for the military	
Aug 2021	19% of employees report having employer vaccine man-	15
	date	
Aug 23, 2021	President Biden's Press Secretary announces more strin-	17
	gent vaccine mandates coming	
Aug 24, 2021	Secretary of Defense announces memorandom to fully vac-	17
	cinate members of the military	
Sept 2021	29% of employees report having employer vaccine man-	18
	date	
Sept 9, 2021	President Biden announces federal vaccine mandates	51

Notes: The above dates were used to construct the common factor variables. We constructed a pure federal vaccine mandate variable, along with a federal-level vaccine mandates variable, which combined the federal vaccine mandates with employer mandates. To construct the continuous federal mandate variable we made the base of the 100 million workers that were predicted to be affected by the September 9th federal vaccine mandates and added 2,395,993, the size of the military. When a signal of upcoming mandates was made the federal mandate variable took on a value of ten percent of those who would be impacted. For example, when the Secretary of Defense sent a message about the intent to implement a military vaccine mandate, the federal mandate variable went from 0 to .0023 (10% of the people who would be impacted by the mandate (members of the military) divided by the base of 102,395,993). When the actual announcement was made, the numerator went to 100% of those impacted by the mandate. The employer mandate variable was equal to whatever percentage of employees reported having vaccine mandates at their place of work each month. The federal level variable was a combination of the two, which became equal to one on September 9, 2021 when President Biden made the vaccine mandate announcement.
